Method for locating an impact on a surface and device therefor

The present invention relates to the methods for
locating an impact on a surface and to the devices for
implementing those methods.

More particularly, the invention concerns a method for
locating an impact on a surface forming part of an
object forming an acoustic interface, provided with at
least one acoustic sensor (the object forming an
acoustic interface may be made of a single piece or of
several elements, assembled or at least in mutual
contact), a method in which at least one signal is
sensed from acoustic waves generated in the object
forming an acoustic interface by said impact and the
impact is located by processing of said sensed signal.

The document FR-A-2 811 107 describes an example of
such a method that applies in particular to a pane. In
this known method, the position of the impact on the
surface of the object is computed by measuring the
differences in time for the acoustic waves to fly to
different sensors.

This known method however requires:
-     that the pane used have a perfect homogeneity and
a perfect surface state,
-     that the fields of the pane be specially treated,
particularly to avoid reflections of the acoustic
waves,
-     that the speed of the acoustic waves in the pane
be known in advance, which assumes a precise knowledge
of its composition,
-     that at least four sensors be used.

As a result, this known method is particularly costly
to implement and cannot be applied to any preexisting

objects, particularly heterogeneous objects consisting of assemblies of pieces, irregular shaped objects, etc.

The aim of the present invention is in particular to alleviate these disadvantages.

For this purpose, according to the invention, a method of the type in question is characterized in that it comprises a recognition step during which the sensed signal is compared with at least one predetermined signal corresponding to the signal that is sensed when an impact is generated on at least one active zone forming part of the surface of the object forming an acoustic interface (this comparison, which can be made both in the temporal domain and the frequency domain, may where appropriate be made on only one portion of the sensed signal or on data extracted from this sensed signal after processing, in which case said predetermined signal may be reduced to the portion on which the comparison is made or to the data on which the comparison is made), and the impact is associated with said active zone if the sensed signal is sufficiently similar to said predetermined signal.

Thanks to these arrangements, a method of locating an impact is obtained which is robust, adaptable to all objects (including heterogeneous objects consisting of assembly of several pieces or of placing several pieces in contact), easy and cheap to apply.

In preferred embodiments of the invention, one and/or other of the following arrangements may also be used where appropriate:
- the surface of the object forming an acoustic interface comprises several active zones and, during the recognition step, the sensed signal is compared with several predetermined signals each corresponding to the sensed signal when an impact is generated on one of said active zones;

- a single acoustic sensor is used;

- several acoustic sensors are used and, during the recognition step, one signal is sensed for each acoustic sensor and the signals sensed by the various acoustic sensors are compared with the predetermined signals independently of one another;

- the signals sensed by the various acoustic sensors are compared with the predetermined signals differently from one another;

- several acoustic sensors are used measuring several different magnitudes;

- at most two acoustic sensors are used;

- the method comprises an initial learning step during which each predetermined signal is determined experimentally by generating at least one impact on each active zone;

- each predetermined signal is a theoretical signal (computed or determined experimentally on an object identical or very similar from the acoustic point of view to the one used);

- during the recognition step, the sensed signal is compared with said at least one predetermined signal by intercorrelation;

- during the recognition step, the sensed signal is compared with said at least one predetermined signal by a recognition method chosen from voice recognition, signal recognition, shape recognition and recognition by neural network;

- during the recognition step, the sensed signal is associated either with a single active zone, or with no active zone;

- each active zone is associated with a predetermined information element (for example, an alphanumeric character, a command, etc.) and, when the impact is associated with an active zone, an electronic device is made to use the predetermined information element corresponding to that active zone;

- the surface of the object forming an acoustic interface comprises a number n of active zones, n being

at least equal to 2, and the recognition step comprises the following sub-steps:

. an intercorrelation is made between the sensed signal (generally after normalization) and said predetermined signals $R_i(t)$, i being a natural integer lying between 1 and n which designates an active zone, and intercorrelation functions $C_i(t)$ are thus obtained,

. a potentially activated active zone j is determined which corresponds to the result of intercorrelation $C_j(t)$ having a maximum amplitude greater than those of the other results $C_i(t)$,

. the distribution $D(i)$ of the amplitude maxima of the intercorrelation results is also determined:

$$D(i) = Max ((C_i(t)),$$

. the distribution $D'(i)$ of the amplitude maxima of the intercorrelation results $C'_i(t)$ between $R_j(t)$ and the various predetermined signals $R_i(t)$ is also determined:

$$D'(i) = Max((C'_i(t)),$$

. a determination is made as to whether the impact was generated on the active zone j as a function of a level of correlation between the distributions $D(i)$ and $D'(i)$;

- during the recognition step, the sensed signal is processed in order to extract therefrom the data representative of certain characteristics of the sensed signal and the data thus extracted is compared with reference data extracted from the signal that is sensed when an impact is generated on each active zone;

- during the recognition step, a code is determined from said data extracted from the sensed signal and this code is compared with a table which gives a correspondence between at least certain codes and each active zone;

- the object forming an acoustic interface comprises at least two active zones and, during the recognition step, the resemblance values representative of the resemblance between the sensed signal and the predetermined signals are determined (especially a

value derived from the intercorrelation function, for example its maximum), the impact is associated with several adjacent active zones corresponding to a maximum resemblance, called reference active zones,

5 then, the position of the impact on the surface is determined as a function of the resemblance values attributed to the reference active zones;

- the position of the impact on the surface is determined such that the resemblance values attributed

10 to the reference active zones correspond as well as possible to theoretical resemblance values computed for said reference active zones for an impact generated in said position on the surface;

- the theoretical resemblance values are a function

15 of the position of the impact on the surface, determined in advance for each possible set of reference active zones;

- the active zone is identified by comparison between the phase of the predetermined signals $R_i(t)$

20 and of the sensed signal;

- during the learning phase, a computation is made of the Fourier transform $R_i(\omega) = |R_i(\omega)|.e^{j\,\phi_i(\omega)}$ of each acoustic signal $R_i(t)$ generated by an impact on the active zone i, where i is an index lying between 1 and

25 n, and from this Fourier transform only the phase component $e^{j\,\phi_i(\omega)}$ is retained, only in the frequency bands ω in which the amplitude $|R_i(\omega)|$ is greater than a predetermined threshold, then the same process is applied to each sensed acoustic signal $S(t)$ during the

30 normal operation of the device;

. the predetermined threshold is equal to the maximum of MAX/D and $|B(\omega)|$, where:

. MAX is chosen from the maximal value of the modules $|R_i(\omega)|$, the maximal value of the modules

35 $|R_i(\omega)|$ each normalized in energy, and the maximal value of the envelope of the average of the modules $|R_i(\omega)|$ each normalized in energy,

. D is a constant,

. $|B(\omega)|$ is the average of several noise spectra in

the object forming an acoustic interface, acquired at
different times;
- during the normal operation of the device:
. a product $P_i(\omega)$ is computed equal to $S'(\omega)$
5 multiplied by the conjugate of $R_i'(\omega)$ for references
$i = 1 \ldots n$,
. then the products $P_i(\omega)$ are normalized,
. then the inverse Fourier transform of all the
products $P_i(\omega)$ is carried out and temporal functions
10 $X_i(t)$ are obtained,
. and the signal $S(t)$ is attributed to an active
zone (10) as a function of said temporal functions
$X_i(t)$;
- the signal $S(t)$ is attributed to an active zone as
15 a function of the maximal values of said temporal
functions $X_i(t)$.

Furthermore, another aim of the invention is a device
especially adapted to implement an interfacing method
20 as defined above.

Other features and advantages of the invention will
emerge from the following description of five of its
embodiments, given as nonlimiting examples, with
25 respect to the attached drawings.

In the drawings:
- figure 1 is a schematic view in perspective
showing an exemplary device comprising an acoustic
30 interface adapted to implement a method according to a
first embodiment of the invention,
- figure 2 is a block diagram of the device in
figure 1,
- figure 3 depicts a graph illustrating an exemplary
35 method used to associate an impact on the surface of
the acoustic interface visible in figure 1, with an
active zone of that surface,
- figure 4 depicts schematically an acoustic
interface that can be used in a device for implementing

a method according to a second embodiment of the
invention,
-   figure 5 is a block diagram of an exemplary device
that can use the input interface of figure 4,
5   -   and figures 6 to 9 depict schematically acoustic
interfaces that can be used in a device for
implementing a method according to third, fourth and
fifth embodiments of the invention.

10 In the various figures, the same references designate
identical or similar elements.

Figure 1 depicts a device 1 intended to implement the
present invention, which comprises for example:
15 -   a microcomputer central processing unit 2,
-   a screen 3 connected to the central processing
unit 2,
-   and an acoustic input interface 4 which is used to
communicate information to the central processing unit
20 2 in the example in question.

The acoustic input interface 4 comprises a solid object
5, consisting here of a table in which acoustic waves
are propagated by generating impacts on its surface 9
25 as will be explained hereafter.

It will be noted however that the object forming an
acoustic interface could consist of any other object,
homogeneous or heterogeneous, made up of a single piece
30 or of several pieces assembled or simply in mutual
contact, such as: pane, door, window, a portable tray,
computer screen, display panel, interactive terminal,
toy, vehicle dashboard, rear of front seat back of
automobile vehicle or of airplane seat, wall, floor,
35 vehicle fenders (the information transmitted by the
acoustic interface then being the position of an impact
on the fenders), etc.

At least one acoustic sensor 6 (only one sensor 6 in

the example shown) is attached to the object 5, this acoustic sensor 6 being connected for example to the microphone input 7 of the central processing unit 2, by means of a cable 8 or by any other means of transmission (radio, infrared or other), so as to sense said acoustic waves and transmit them to the central processing unit 2.

The acoustic sensor 6 may for example be a piezoelectric sensor or other (for example a capacitive sensor, a magnetostrictive sensor, an electromagnetic sensor, an acoustic velocimeter, an optical sensor [laser interferometer, laser vibrometer, etc.], etc.). It may be suitable for measuring for example the amplitude of the movements due to the propagation of the sound waves in the object 5 forming an acoustic interface, or the speed or acceleration of such movements, or it may involve a pressure sensor measuring the pressure variations due to the propagation of the acoustic waves in the object 5.

On the external surface 9 of the object 5 (in this instance on the upper face of the table forming said object 5 in the example shown in figure 1), several active zones 10 are defined which can be delimited for example:
-      by a physical marking, removable or not, affixed to the surface 9 of the object 5,
-      or by a luminous marking obtained by projecting an image onto the surface 9.

The surface 9 could also comprise portions in which the generation of an impact would be forbidden for example by covering them with a material that is flexible or simply inaccessible to the user, particularly for better reliability of the system.

The various active zones 10 may simply be portions of the surface 9, identical to the rest of the surface 9.

These active zones are however differentiated from one another and from the rest of the surface 9 to the extent that an impact on one of the zones 10 generates an acoustic signal different from the signal generated
5   by an impact on another of the active zones 10 or on another portion of the surface 9.

Each of the active zones 10 is associated with a predetermined information element that a user may wish
10   to communicate to the central processing unit 2. The information in question may for example be a command, a digit, a letter, a position on the surface 9, or any other information that can be habitually transmitted to an electronic device such as a microcomputer (or to the
15   central processing unit of another electronic apparatus) by means of the conventional input interfaces such as keyboards, control buttons, mice or other.

20   The information in question may, where appropriate, be indicated in clear by the markings 10a on the surface 9 (as for the identifiers of the zones 10, these markings may be affixed physically to the surface 9 in a permanent or removable manner, or they may be projected
25   in the form of luminous images onto said surface 9).

As a variant, the surface 9 of the object 5 may simply comprise identifiers (physically affixed or luminous) to distinguish the active zones from one another. These
30   identifiers may for example be numbers or colors and a reminder of their meaning may where necessary be given by a display generated by the central processing unit 2 on the screen 3.

35   Where necessary, the surface 9 may also comprise no marking, either to delimit the active zones, or to identify the information to which they correspond, in which case the active zones 10 would be known only to the authorized users of the device 1.

It will be noted that the predetermined information elements associated with each active zone 10 may either be always the same or vary as a program runs in the central processing unit 2, or depend on previous actuations of other active zones 10 (certain active zones 10 may for example be actuated to change the function attributed to one or more active zone(s) 10 actuated after it, so as, for example, to access specific functions, special characters, or to put letters in upper case, etc.).

The various active zones 10 of the object 5 therefore constitute a true virtual keyboard that is actuated by hitting the active zones with a fingernail, with the fingertips, with an object such as a pen, stylet or other.

It will be noted that the surface 9 of the object 5 could, where appropriate, comprise a single active zone 10 in the simplest cases, this active zone 10 however not extending to the whole surface 9 and preferably constituting a small portion of said surface 9.

As shown in figure 2, the sensor 6 (SENS.) may conventionally be connected via the input 7 to an amplifier 11 itself connected to an analog/digital converter 12 (A/D) which transmits the received signals to the processor 13 of the central processing unit 2 (CPU) which processor is in turn connected to one or more memories 14 (MEM.) and commands the abovementioned screen 3 (SCR.) or any other output interface sending information to the user.

It will be noted that the acoustic interface 4 could serve as an interface for inputting information to any electronic devices other than a microcomputer, for example a domestic or business electronic apparatus, a digicode, a vehicle electronic central processing unit,

etc. In all cases, the electric signals generated by the sensor or sensors 6 may be processed either in this electronic apparatus or in an external digital signal processing device (DSP).

During the use of the device 1 described above, when a user generates an impact on the surface 9 of the object 5, this impact engenders an acoustic wave which is propagated in the object 5 to the acoustic sensor 6. The acoustic sensor 6 then generates an electric signal $S(t)$ which, after digitization, is processed by the processor 13 (or by another dedicated processor, inside or outside the central processing unit 2).

The processor 13 then compares the received signal with the various predetermined signals belonging to a library of signals previously stored in the memory 14, these predetermined signals corresponding respectively to impacts generated on the different active zones 10 of the object 5.

This comparison is used to ascertain whether the acoustic signal originates from one of the active zones 10, and which, irrespective of the mode of excitation of said active surface (impact of a fingernail, of a fingertip, of the palm of a hand, of an object such as a pen or a stylet, etc.).

These predetermined signals from the library of signals may have been determined during an initial learning phase in which impacts are generated successively on all the active zones 10 of the object 5, by recording the corresponding signals (preferably after normalization, for example so that the energy of each reference signal is equal to 1) received in the central processing unit 2 via the acoustic sensor 6.

As a variant, when the object 5 has a simple and/or repetitive geometric shape, it is possible for the

predetermined signals from the library of signals to be obtained by modeling or determined experimentally only once for all the objects 5 of a series of identical objects: in these two cases, there would therefore not be a prior learning phase for the particular object 5 connected to the central processing unit 2, but simply installation of the library of signals in the memory 14 of said central processing unit.

It will be noted that, in some cases (particularly if the object 5 is made of wood), the predetermined signals from the library of signals may be made to vary according to the ambient conditions, particularly the temperature and the humidity. These variations may be computed or be the result of a new learning phase.

The signals received during the use of the device 1 can be compared with the predetermined signals from the library of signals:
- directly on the temporal signals $S(t)$ received from the sensor 6,
- or on the frequency spectrum of these signals (for example after Fourier transform of the temporal signals received from the sensor 6),
- or on other data characteristic of the signal, particularly its phase.

The sensed signals can be compared with the predetermined signals from the library of signals by any known means, in particular:
- by intercorrelation,
- by known methods of voice recognition, of signal recognition or of shape recognition,
- by the use of neural networks or others.

As a more precise example, the following method can in particular be used to recognize the active zone 10 from which the sensed signal $S(t)$ comes:
(1) after normalization of the sensed signal $S(t)$ (for

example S(t) is calibrated so that its energy is equal to 1), the signal S(t) generated by the sensor 6 is intercorrelated with the n predetermined signals also normalized from the library, denoted $R_i(t)$ where

5   i = 1..n. Functions $C_i(t)$ are thus obtained that are the temporal results of the product of intercorrelation of the signal S(t) respectively with the signals $R_i(t)$ from the library. Based on these computations is determined a potentially activated active zone j

10   corresponds to the result of intercorrelation $C_j(t)$ having a maximum amplitude greater than those of the other results $C_i(t)$.
     (2)   The distribution D(i) of the amplitude maxima of the intercorrelation results is also determined:

15   $D(i) = Max((C_i(t))$ where i = 1..n.
     (3)   A second distribution function D'(i), obtained in the same manner as the computation of the function D(i) but replacing S(t) with $R_j(t)$, is computed.
     (4)   An intercorrelation is carried out of the

20   distributions of the amplitude maxima D(i) and D'(i). If the maximal amplitude E of the result of intercorrelation between D(i) and D'(i) is sufficient, then j is the considered number of the activated zone. Otherwise, the signal generated by the sensor

25   corresponds to a false alarm.

During this step (4), E and the maximal value of D(i), or Max(D(i)) can simply be computed: if these two values are considered to be the coordinates of a point

30   in a two-dimensional space of axes x=Max(D(i)) and y=E, as shown in figure 3, a curve threshold L can be determined in advance (empirically or by computation) which delimits a domain D corresponding to the validated points (this domain is finite and limited at

35   x=1 and y=1, absolute maximal values of D(i) and E). The sensed signals which give points outside the domain D, for their part, are eliminated as being false alarms.

In the example in question, the line D is a straight line which can pass for example through the points (S1, 0) and (0, S2). For example, S1=0.4 and S2=0.4 or 0.6.

5   It will be noted that in addition to identifying the active zone 10 from which the impact comes, it would be possible to measure the force of the impact, for example in order to guide the user in how to use the acoustic interface, or to modulate the action triggered

10   by an impact on an active zone 10, according to the intensity of that impact.

It will be noted furthermore that the signals originating from the active zones 10 may, where

15   necessary, be recognized by using only a portion of the received signals S(t) or a portion of their frequency spectrum or more generally a portion of their characteristics. In this case, during the recognition step, the sensed signal is processed in order to

20   extract from it data representing certain characteristics of the sensed signal and the data thus extracted is compared with reference data extracted from the signal which is sensed when an impact is generated on each active zone.

25

Thus, it is for example possible to measure the amplitude and the phase of the signal for m predetermined frequencies (m being a natural integer at least equal to 1) and to compare these measured

30   amplitudes a1-am and these measured phases p1-pn with the measured amplitudes $Ai1-Aim$ and the measured phases $Pi1-Pim$ at said predetermined frequencies based on signals received during the learning phase (or determined by modeling) for the various active zones 10

35   numbered i (i being between 1 and n, where n is the number of active zones 10).

As a variant, it is possible to determine a code from said data extracted from the sensed signal and to

compare this code with a table which gives a correspondence between at least certain codes and each active zone (the codes contained in this table then represent the predetermined signals from the
5   abovementioned library of signals).

As a nonlimiting example, a 16-bit code can be determined from the sensed signal S(t) in the following manner:
10   -   the first 8 bits of the code are determined from the frequency spectrum of the signal S(t) that is subdivided into 8 predetermined frequency tranches $[f_k, f_{k+1}]$, k=1..8: the bit of rank k is equal to 1 for example if the final energy value given by the spectrum
15   at frequency f_{k+1} is greater than the average energy value of the acoustic wave in the frequency tranche $[f_k, f_{k+1}]$ and this bit is 0 otherwise;
-   the last 8 bits of the code are determined from the temporal signal S(t) that is subdivided into 9
20   predetermined temporal tranches $[t_k, t_{k+1}]$, k=1..9: the bit of rank k+8 is equal to 1 for example if the average value of the signal power during the period $[t_k, t_{k+1}]$ is greater than the average value of the signal power during the period $[t_{k+1}, t_{k+2}]$, k=1..8, and
25   this bit is 0 otherwise.

In this particular example, the codes in the correspondence table would be determined during the learning phase, by computing as indicated above the
30   codes that correspond to the signals sensed by the acoustic sensor 6 when impacts are generated on the different active zones 10.

Furthermore, as shown in figures 4 and 5, it may be
35   possible to use two acoustic sensors 6 (SENS.1 and SENS.2), particularly when the object 5 has symmetries such that there may be a risk of confusion between the signals originating from two different active zones 10. Where appropriate, more than two acoustic sensors 6 may

be used, although the preferred solutions call for one
or two sensors 6.

When two or more sensors are used, two choices are
possible:
1)   mixing of the signals of the various sensors and
processing of the global signal according to the method
described above,
2)   or, preferably, individual processing of the
signals of the various sensors with the method
described above and a cross-checking of the results:
-      if the active zones 10 determined from the various
sensors have identical numbers, then it is determined
that the zone that received an impact is the latter,
-      in the other cases, it is possible either to
consider the sensed signal to be a false alarm or to
determine the zone that received an impact for example
by intercorrelation between the intercorrelation
functions $C_i(t)$ determined for each sensor or by more
complex means such as neural networks or others.

It will be noted that the two acoustic sensors may be
of different types and/or sense different magnitudes
and/or their signals may be processed differently to
identify the active zones 10 receiving impacts. For
example, one of the acoustic sensors may be used to
record the received signal $S(t)$, while the other may be
used only to determine a temporal difference between
the arrival of the acoustic wave at the two sensors.

The second sensor might furthermore not sense the
acoustic wave propagated in the solid object 5, but the
acoustic wave propagated in the air at the time of the
impact.

As shown in figure 6, the object forming an acoustic
interface may consist of the computer screen 3 or a
television screen to which the sensor 6 is attached.
The surface receiving the impacts may advantageously be

the pane 15 of the screen, which could in particular be used to have the screen 3 display the delimitation of the active zones 10 and their meaning. This variant could be used for example to program a video cassette
5   recorder, particularly when the screen 3 is a television screen (the central processing unit 2 would then be replaced by the video cassette recorder).

As shown in figure 7, the object forming an acoustic
10   interface may also consist of a glass paneled door 16 or similar. In the example shown in figure 7, the surface 17 which supports the active zones 10 consists of the glazed surface of the door, and, still in the particular example shown in this figure, the acoustic
15   sensor 6 is attached to a wooden portion of the door 16.

In the example shown in figure 8, the object forming an acoustic interface is a tray 18 designed especially to
20   serve as an acoustic interface. This tray may for example comprise a rigid frame 19 secured to a base 20, also rigid, which supports the acoustic sensor 6.

A flexible membrane 22, made for example of elastomer,
25   is stretched over the frame 19 a short distance above the base 21. This flexible membrane 22 is provided with rigid protrusions 23 under its bottom face (these may for example be glass hemispheres that are bonded beneath the membrane 22). Thus, when a user taps on the
30   membrane 22 and particularly on an active zone 10 supported by this membrane, this action generates an impact of at least one protrusion 23 on the bottom 21 of the frame of the tray 18. This variant has the advantage of producing impacts that are less dependent
35   on the manner in which the user taps on the membrane 22 (with the finger or the nail or a tool, with more or less force, etc.).

In the embodiments in figures 6 to 8, the method

implemented may be identical or similar to that
described previously and may be used to provide a
correspondence of an impact generated on the surface of
the object forming an acoustic interface either with an
5   active zone 10 or with no active zone.

But it is also possible, in all the embodiments of the
invention using several active surfaces (point-like
where necessary), to determine the position of the
10   impact on the surface 9 of the object 5 forming an
acoustic interface (see the example in figure 9), even
when that impact is not on one of the active zones. A
continuous or pseudo continuous acoustic interface is
thus obtained (making possible an operation similar for
15   example to a computer mouse, to a light pen, to a
touch-sensitive screen or similar).

In this case, during the recognition step:
-    resemblance values representative of the
20   resemblance between the sensed signal and the
predetermined signals are determined (particularly
values originating from the abovementioned
intercorrelation functions $C_i(t)$, for example their
maxima $D(i)$ defined above),
25   -   the impact is associated with a number p at least
equal to 2 of adjacent active zones corresponding to a
maximum resemblance, called reference active zones R1-
R4 (p may advantageously be 4 particularly for
positioning the impact according to two dimensions x,
30   y, or where appropriate less than 4 particularly if the
impact is to be positioned only according to a single
dimension x or y): for example, the zone R1 can first
be determined as being the active zone 10 having the
maximal resemblance value $D(i)$, and then, from the
35   active zones adjacent to R1, the three zones R2-R4 can
be determined which give the highest values of the
resemblance value $D(i)$);
-    then the position of the impact I on the surface 9
is determined as a function of the resemblance values

D(i) attributed to the reference active zones R1-R4.

During this last step, advantageously it is possible to determine the position of the impact on the surface such that the resemblance values attributed to the reference active zones correspond as well as possible to theoretical resemblance values computed for said reference active zones for an impact generated in said position on the surface.

These theoretical resemblance values may in particular be functions of the position of the impact on the surface, determined in advance for each possible set of reference active zones.

The functions in question may be determined during the learning step, for example by adjusting a typical function on the values of resemblance between the active zones. The typical function in question may depend on the shape of the object and be determined in advance, either theoretically or experimentally.

To take a practical example, the function of theoretical resemblance Rth(X,Y) between two points X, Y of the surface 9 may correspond to the maximum of the function of intercorrelation between the signals Sx(t) and Sy(t) sensed by the sensor 6 respectively when impacts are generated at these two points X, Y, and this function may for example be of the type $Rth(X, Y) = (\sin(a(\beta).d)) / (a(\beta).d)$, approximated for example by $Rth(X, Y) = 1 - [a(\beta).d]^2/6$, where:

-    d is the distance between X and Y,
-    β is an angle between for example the x axis (or y axis) and the direction X-Y,
-    and a(β) is a coefficient dependent on the angle β according to an elliptical function:
$a(\beta) = a1.\cos(\beta+\beta0) + a2.\sin((\beta+\beta0)$,
where β0 is an angle representative of the orientation of the ellipse.

The Rth function can be determined for each possible set of active reference zones R1-R4, from predetermined signals Ri(t) from the library of signals, sensed by generating impacts respectively on the reference active zones during the learning phase.

Accordingly, for a given set of four reference zones R1-R4, the maximum intercorrelation function of the signal R1(t) corresponding to R1 can be computed, with each of the signals R2(t), R3(t), R4(t) corresponding to the zones R2-R4. From this are deduced the values of a1, a2 and $\beta 0$. The same process can then be performed from the reference zones R2, R3 and R4, which on each occasion gives the values of a1, a2 and $\beta 0$, then the average of the four values thus found respectively for a1, a2 and $\beta 0$ can be averaged: these averaged values then determine the function Rth for all the reference zones R1-R4. As a variant, the function Rth could be determined by an iterative optimization process (of the least squares method type) to minimize a function of error between the function of theoretical resemblance and the maxima of the functions of intercorrelation between the signals R1(t), R2(t), R3(t) and R4(t) taken two at a time.

When the abovementioned theoretical resemblance functions Rth have been determined, when seeking to determine the position of an impact I between four adjacent active zones R1-R4 (advantageously point-like), this position can for example be determined by an iterative optimization process by minimizing a function of error between the values D(i) previously defined (D(i)=Max(Ci(t)), with i here being the number of the reference active zone Ri in question) and the values of theoretical resemblance Rth(I, Ri). For example, a function of error E equal to the sum of the values $(D(i)-Rth(I, Ri))^2$ can be minimized.

The method that has just been described is of course
not limited to the examples that have just been
described; it has many applications, amongst which:

- the use of panes or other surfaces as an input
5   interface 4, in shops, museums, art galleries, or other
places to allow the clients or the visitors to display
details on a screen or via a loudspeaker concerning the
products or works exhibited,

- the use of panes or other surfaces of display
10 panels as input interfaces 4, allowing passers-by to
display for example details on the publicity items
being displayed, or to display general information
concerning a community or another place (for example
news or practical information, for example a plan of
15 the location), or other, these details or information
being displayed for example on a screen visible in the
lower portion of the display panel,

- the use of portions of walls, of the ground, or of
any other object as an input interface 4 for example
20 for controlling home automation systems (residents of
an apartment can thus in particular themselves
determine the positions of the switches, consisting
simply of the abovementioned active zones 10,
positioned on the walls or other places as required),

25 - the use of portions of walls, of the ground, or of
any other object as an input interface 4 for example
for controlling industrial machines particularly in
dangerous environments (places containing explosives,
places with high temperature, places with high
30 radioactivity, etc.),

- the use of smooth and easily maintained surfaces
as an input interface 4, in order to constitute input
keyboards of domestic objects such as refrigerators,
washing machines or other,

35 - the use of panels on building doors as input
interfaces 4, forming for example virtual digicode
keyboards,

- the use of the ground to locate the position of a
person walking on it,

-    the production of keyboards or control panels unaffected by pollution, bad weather or other external attacks, in industrial, military or even domestic applications (the acoustic sensor or sensors may where necessary be fully integrated into the object serving as the input interface, in particular if it is an object at least partially molded in plastic material); when these input interfaces are to control a device (for example a microcomputer), comprising a display screen, the keyboard or acoustic control panel may consist of the screen itself or a transparent surface covering that screen,

-    the production of input interfaces in automobiles or other vehicles.

It will furthermore be noted that the previously described input interface 4 could be provided with processing means for locally performing the recognition of acoustic signals S(t) originating from the active zones 10, the input interface 4 then sending directly to the central processing unit 2, or to any other user electronic apparatus, only coded signals indicating directly which active zone 10 has been touched by the user and, where appropriate, information relating to the impact: force of the impact and nature of the impact.

It will be noted that the method according to the invention does not require the object 5 to have a homogeneous or predetermined structure, or be made with a particular care, or be made with very precise dimensions, or with specific surface states. On the contrary, the more the object 5 is heterogeneous and/or irregular, the more the acoustic signals emitted by the different active zones 10 will be different from one another and the better the acoustic signals will be recognized. In certain cases, heterogeneities can even be intentionally created such as cavities or others in the object 5 to facilitate recognition of the acoustic

signals originating from the active zones 10.

Furthermore, when the predetermined signals from the library of signals are determined during a learning phase, it is possible to use a piezoelectric sensor connected by any known means to a central processing unit 2 and fixed either to the finger of the user, or to the object (stylet or other) used to generate impacts on the active zones of the object 5. In this case, the impulse signal generated by the piezoelectric sensor at the time of each impact can be used to trigger the acquisition of the predetermined acoustic signal intended to feed the library of signals, and/or can be used to measure the intensity of the impact, this measurement of intensity being able to be used for example to invalidate certain acquisitions of predetermined signals in particular when the intensity is below a predetermined threshold or when this intensity does not fall within a predefined period.

Furthermore, when the predetermined signals from the library of signals are determined during a learning phase, it may be advantageous to retain only the sensed acoustic signals whose amplitude is greater than a relatively high first reference threshold. In this case, during the normal operation of the device, account can thereafter be taken of the acoustic signals whose amplitude exceeds a second predetermined threshold clearly lower than the first threshold. The first predetermined threshold may thus be equal to several times (at least two to three times) the average temporal value of the absolute amplitude of the ambient noise, measured for example over several seconds, whereas the second predetermined threshold may for example be equal to 1.5 times that average value. In this manner, only good quality reference signals are recorded during the learning phase, while retaining a great sensitivity of the device during its normal operation.

Where appropriate, the central processing unit 2 may be provided with an auxiliary programming keyboard (not shown) which may be used in particular during the learning phase to indicate for example what type of signal is generated. This type of generated signal may in particular be one of the following types:

-       new signal replacing one of the reference signals from the library of signals (the identification of the replaced reference signal may thus be communicated to the central processing unit 2 by means of the auxiliary keyboard),

-       new reference signal (either for a preexisting but incomplete reference library, or for a new reference library corresponding in particular to new conditions of temperature, humidity or state of the object 5),

-       new signal intended to verify a reference signal that already exists in a library of signals.

Furthermore, when the predetermined signals from the library of signals are determined during a learning phase, provision may be made where appropriate to validate the reference signals from that library only when they are confirmed by generation of one or more impact(s) on the same active zone, within a predetermined elapsed time following the generation of a first impact.

When the predetermined signals from the library of signals are determined during a learning phase, the impacts generated on the object 5 during this learning phase may be generated:

-       either with a hard object such as a stylet, in which case the same stylet will preferably be used during the normal operation of the device,

-       or with a more shock-absorbent object such as for example a hard plastic rubber attached to the end of a pen or similar (the inventors have thus been able to obtain good results with a "Staedler" brand of hard

plastic rubber for transparencies), in which case the impacts on the object 5 may then be generated just as well with relatively hard objects as with less hard objects (fingernail, finger pad or other) during the normal operation of the device.

Furthermore, as a variant of the method previously described to recognize the active zone 10 from which the sensed signal S(t) comes, it is possible to use the following method:

(1) during the learning phase, the Fourier transform $R_i(\omega)$ is computed for each acoustic signal $R_i(t)$ generated by an impact on the active zone i, where i is an index lying between 1 and n:

$$R_i(\omega) = |R_i(\omega)| . e^{j \phi_i(\omega)}$$

From this Fourier transform, only the phase component is retained, only in the frequency bands ω in which the amplitude of the spectrum is greater than a predetermined threshold.

The frequency shape of the reference signal retained is therefore expressed in the form $R'_i(\omega) = e^{j \phi_i(\omega)}$ for the frequencies ω at which $|R_i(\omega)|$ is greater than the predetermined threshold and $R'_i(\omega) = 0$ at the other frequencies ω.

The predetermined threshold in question may for example be equal to the maximum of MAX/D and of $|B(\omega)|$, where:

- MAX may be either the maximal value of $|R_i(\omega)|$, or the maximal value of the modules $|R_i(\omega)|$ each normalized in energy, or the maximal value of the envelope of the average of the modules $|R_i(\omega)|$ each normalized in energy,

- D is a constant, for example equal to 100,

- $|B(\omega)|$ is the average of several noise spectra in the object 5, acquired at different times.

(2) During the normal operation of the device, each

sensed signal $S(t)$ undergoes the same process as in step (1) above, such that a signal $S'(\omega) = e^{j\psi(\omega)}$ is obtained for the frequencies ω at which $|S(\omega)|$ is greater than the abovementioned predetermined threshold, $S'(\omega)$ being equal to 0 at the other frequencies.

(3) Then a product $Pi(\omega)$ is computed equal to $S'(\omega)$ multiplied by the conjugate of $R'(\omega)$ for $i = 1 \ldots n$.

(4) The products $P_i(\omega)$ are normalized by dividing them by their integrals.

(5) Then the inverse Fourier transform of all the products $P_i(\omega)$ is carried out and temporal functions $X_i(t)$ are obtained.

According to the different functions $X_i(t)$, and particularly according to their maximum, the signal $S(t)$ can then be attributed to one of the active zones 10. As an example, the maximal value (as a relative value or absolute value) can be computed of the different functions $X_i(t)$ and the signal $S(t)$ can be attributed to the active zone i which corresponds to the function $X_i(t)$ with the greatest maximum. Where necessary, the maximum of the function $X_i(t)$ retained can also be compared with a threshold defined in advance, for example equal to 0.6, and it can be decided that the signal $S(t)$ should be attributed to the zone i when the maximum of $X_i(t)$ is greater than this threshold (if several functions $X_i(t)$ have their maximum greater than 0.6, only the function $X_i(t)$ with the greatest maximum is then retained).

It is possible where necessary to verify that the attribution of the signal $S(t)$ to the active zone i is correct, for example by computing a value $MM_i = M_i/M$ where M_i is the maximum of the absolute value of $X_i(t)$ and M is the average value of all the values M_i. The

attribution of the signal S(t) to the active zone i may then be considered to be correct if that value MM_i is greater than a certain limit, equal for example to 1.414.

5

It will also be noted that the abovementioned values MM_i may be computed by replacing $S'(\omega)$ with $R'_i(\omega)$, in order to obtain information on the spatial resolution of the active zones. In particular, it can thus be

10 verified that an active zone with index i does not risk being confused with another, by verifying that the corresponding value MM_i is greater than a predetermined limit, for example greater than 1.414.

15 Furthermore, it is also possible to take account of different environmental parameters (temperature, relative humidity, mechanical stresses, etc.) by modifying the predetermined signals from the library of signals as a function of the environmental parameter or

20 parameters.

Accordingly, use can be made of one of the following correction methods:
-       linear temporal dilation or contraction of the

25 reference signals from the library of signals: in this case, the reference signals $R_i(t)$ from the library of signals are replaced by signals $R_i(\alpha t)$, where α is a non null positive multiplier coefficient which is a function of the environmental parameters, this

30 coefficient α being able to be determined theoretically or experimentally for a given material, or experimentally for each object 5;
-       linear temporal dilation or contraction of the sensed signals S(t): in this case, the reference

35 signals $R_i(t)$ are left unchanged, but the sensed signal S(t) is replaced by $S(\alpha t)$ where α is a coefficient as defined above;
-       nonlinear dilation or contraction in frequency of the reference signals: in this case, the frequency

signals $R'_i(\omega)$ are replaced by $R'_i(\omega')$, with $\omega' = \dfrac{\omega\beta^2}{1+\sqrt{(\omega/\omega_N).(\beta-1)}}'$ where ω_N is equal to half the sampling frequency of the processing device, and β is a coefficient determined theoretically or experimentally;

5   - nonlinear dilation or contraction in frequency of the sensed signal $S(t)$: in this case, the reference signals from the library of signals are left unchanged, and the signal $S'(\omega)$ is replaced by $S'(\omega')$, ω' being defined above.

10

In the two abovementioned cases of nonlinear dilation or contraction in frequency, it is possible also to use an averaged correction of phase, in which case the signals $R_i(\omega')$ are replaced by $R_i(\omega')$. $M'(\omega)/N'(\omega)$ or

15   the signals $S(\omega')$ are replaced by $S(\omega')$. $M'(\omega)/N'(\omega)$. In one or other of these formulae, $N'(\omega)=M(\omega)/|M(\omega)|$, and $N'(\omega)=N(\omega)/|N(\omega)|$, $M(\omega)$ being equal to the average of all the $R_i(\omega)$ and $N(\omega)$ being equal to the average of all the $R_i(\omega')$.

20

The various abovementioned corrections of the reference signals $R_i(\omega)$ or of the sensed signal $S(\omega)$ may be made either automatically by the central processing unit 2, particularly as a function of information given by one

25   or more sensors (not shown), or manually by the user.

Furthermore, it will be noted that the central processing unit 2 may comprise several libraries of reference signals suitable for different values of the

30   environmental parameters.

Furthermore, to suit the types of impacts generated when the device is used, and particularly to suit the use either of a finger of the user, or of another

35   object to generate the impacts, it may be advantageous to request the user to generate impacts on one or more predetermined active zones 10, for example two active zones of indices m and p. Thus two temporal signals

$S_m(t)$ and $S_p(t)$ are sensed, their Fourier transforms $S_m(\omega)$ and $S_p(\omega)$ are computed and then the average $M_1(\omega)$ of the following two terms is computed:

-     $(R_m(\omega).|S_m(\omega)|)/(|R_m(\omega)|.S_m(\omega))$,
-    and $(R_p(\omega).|S_p(\omega)|)/(|R_p(\omega)|.S_p(\omega))$.

This average $M_1(\omega)$ is then used in step (3) previously defined to replace the product $P_i(\omega)$ with $M_1(\omega).P_i(\omega)$, this product then being used instead of $P_i(\omega)$ in step (4).

Furthermore, it will be noted that the invention allows a user to define active zones at will and the central processing unit 2 may be suitable for keeping active this definition of the active zones only when the object 5 is effectively being used as an acoustic interface. In this case, the abovementioned definition of the active zones is erased by the central processing unit 2 after a certain period of nonuse of the device.

It will also be noted that the function generated by an impact on an active zone may be modulated where appropriate as a function of the intensity of that impact.

It will also be noted that, when the object 5 exhibits resonance phenomena which cause prolonged propagations of acoustic waves on each impact on the active zones, it may be advantageous to raise the threshold of detection of the acoustic signals $S(t)$ (for example up to 0.5 times the maximal value admissible by the electronic system for acquisition of the signal $S(t)$) when a signal $S(t)$ has been detected, then to lower this detection threshold again (notably in exponential manner) to its normal level: thus, multiple detections of one and the same impact are avoided.

It will be noted that, in all the embodiments of the invention, it would where necessary be possible to

define a single active zone on the object 5, in which case it is nevertheless possible to code several functions on that single active zone, for example according to the number of impacts generated
5 consecutively on the same zone.

Furthermore, the active zones 10 may where necessary not be defined in advance, but simply be defined as a function of the successive impacts received during the
10 use of the device. Thus, the device can for example be designed to comprise three active zones, which are each simply defined on the receipt of a first impact on each zone, and which are then recognized as "first zone", "second zone", and "third zone", on receipt of the
15 subsequent impacts.

Furthermore, when the active zones are very numerous, use can be made where necessary of an automated device to generate the reference signals stored in the library
20 of signals during the learning phase. This automated device could for example comprise a system of movement on two dimensions, comprising two step motors, to move for example an excitation stylet or similar to the surface of the object 5 and to generate impacts by
25 means of this stylet, actuated for example by a solenoid, on the various active zones.

Still in the situation where the active zones 10 are extremely numerous, it may be possible to divide them
30 into several resemblance groups. In this case, during normal use of the device, when an impact generates a signal S(t), a first process is used to attach this signal S(t) to one of the resemblance groups, then a refined process is used to assign this signal S(t) to
35 one of the active zones in this resemblance group.

It will also be noted that the same central processing unit 2 could where necessary process the signals originating from several objects 5. In addition, it is

also possible to interface the acoustic sensor or sensors directly with a network, particularly an IP network, in order to direct the sensed signals to a single IP address from which these signals can be exploited by any computer connected to the IP network.
